MAGNETIC RESONANCE APPARATUS

This is a continuation of copending application Ser. No. 07/441,637 filed on Nov. 27, 1989, now abandoned. 5
This invention relates to magnetic resonance (MR) apparatus.

MR apparatus includes, inter alia, a magnet system for producing a homogeneous static magnetic field of high strength in which the object to be examined, e.g. 10 imaged, is positioned during examination, and which serves to define an equilibrium axis of magnetic alignment of nuclei within the object.

One particular application of MR apparatus is the examination of patients for medical diagnostic purposes. 15 Such apparatus is often designed so as to be capable of examining any desired part of the whole body of a patient. The magnet system of such a so-called "whole body" MR apparatus is necessarily quite bulky and where, as is normally the case, the patient is inserted 20 into the apparatus whilst lying horizontally in the direction of the head-to-toe axis of the patient, the MR apparatus together with the associated patient handling equipment requires a large floor area to accommodate 25 it, i.e. has a large so-called "footprint".

It is an object of the present invention to provide an MR apparatus wherein this problem is alleviated.

According to the present invention there is provided an MR apparatus including a magnet system including a magnetic core arrangement which is shaped so as to provide in a gap between a pair of opposed surfaces of the core arrangement a static magnetic field for defining an equilibrium axis of magnetic alignment of nuclei within an object under examination; and an object handling equipment including an object support member of elongated form adapted to support an object for examination and capable of translational movement in a plane transverse to the direction of the magnetic field in said gap in a direction transverse to the longitudinal axis of 40 said support member, the extent of said movement being sufficient to allow an object on said support member to be moved between a position within said gap and a position substantially wholly outside said gap. 35

Typically said plane is orthogonal to said magnetic 45 field direction.

Preferably said support member is further capable of translational movement in said plane in a second direction at an angle to the first-mentioned direction of translational movement at least when said support member is 50 at a position such that said object is within said gap.

Preferably said first-mentioned and second directions are respectively orthogonal to and parallel to said longitudinal axis.

In one particular embodiment of the invention said 55 support member is capable only of translational movement in said plane.

In another particular embodiment of the invention said support member is also capable of rotational movement about axes normal to said plane. 60

Where the apparatus is a whole body MR apparatus for examining patients, said support member is suitably adapted to support a patient whilst lying horizontally with the head-to-toe axis of the patient parallel to said longitudinal axis of the support member. 65

Several MR apparatuses in accordance with the invention will now be described, by way of example, with reference to the accompanying drawings in which:

FIG. 1 is a schematic diagram showing the general arrangement of all the apparatuses to be described;

FIG. 2 is a diagram illustrating a magnetic core arrangement of a magnet system of a first apparatus according to the invention;

FIGS. 3, 4 and 5 are respectively diagrammatic plan, side and end views of the magnetic core arrangement and a patient handling equipment of the first apparatus;

FIG. 6 is a diagram illustrating an alternative form for the magnetic core arrangement of the first apparatus;

FIG. 7 is a diagram illustrating a magnetic core arrangement of a second apparatus in accordance with the invention;

FIG. 8 is a diagrammatic plan view of the magnetic core arrangement and a patient handling system of the second apparatus; and

FIGS. 9 and 10 are respectively diagrammatic plan and side views of a magnetic core arrangement and patient handling equipment of a third apparatus according to the invention.

Referring to FIG. 1, the apparatuses, which are diagnostic patient imaging apparatuses, include an electromagnet which produces a strong uniform static main magnetic field B_0 across a gap between two pole pieces

25 1 of a magnetic core arrangement of the electromagnet, the pole pieces 1 being joined by a yoke (not shown in FIG. 1) carrying an energising coil (not shown). In use of the apparatus a patient 3 to be imaged is placed in the gap between the pole pieces lying horizontally on a support member of a patient handling equipment (not shown) so that the head-to-toe axis of the patient 3 is orthogonal to the direction of the magnetic field in the gap. The strength of the field in the gap between the pole pieces 1, and hence in the patient's body, is controlled by a computer 5 via a main magnet control means 7 which controls the supply of energising current to the electromagnet energising coil.

The apparatus further includes a gradient coil system 9 whereby a gradient may be imposed on the static 40 magnetic field in the gap between the pole pieces 1 in any one or more of three orthogonal directions. The coil system 9 is energised by a gradient field control means 11 under control of the computer 5.

The apparatus further includes an r.f. antenna system 45 13.

The antenna system 13 is selectively connectable by way of a transmit-receive switch 15 either to an r.f. transmitter 17 or a receiver 19. The transmitter 17 is operated under control of the computer 5 to apply r.f. 50 field pulses to the patient's body 3 for excitation of magnetic resonance in the patient's body 3. R.f. signals resulting from magnetic resonance excited in the body are sensed by the antenna system 13 and passed via the receiver 19 to an imager 21 which under control of the computer 5 processes the signals to produce signals representing an image of the body 3. These signals are, in turn, passed to a display device 23 to provide a visual display of the image.

In operation of the apparatus the field provided by 60 the electromagnet defines an equilibrium axis of magnetic alignment in the body 3.

To obtain an image of a selected region, e.g. a cross-sectional slice of the patient's body 3, an r.f. field pulse is first applied to the body 3 by means of the r.f. transmitter 17 and antenna system 13 to excite magnetic resonance in the selected region. To this end the antenna system 13 produces a field B_1 in a direction orthogonal to the static field direction so as to tip the spins

of nuclei in the selected region from the direction of the static field into a plane orthogonal to the static field direction. To restrict excitation to the selected region the r.f. field pulse is applied in conjunction with magnetic field gradients imposed by the coil system 9, the frequency of the r.f. field being chosen in conjunction with the magnitudes and directions of the imposed gradients so that the Larmor frequency of chosen protons in the body, e.g. hydrogen protons, is equal to the r.f. field frequency only in the selected region.

The r.f. signals resulting from excitation are then spatially encoded by application of one or more further gradient magnetic fields in known manner, detected by the antenna system 13 and processed to produce an image.

Normally a number of excitation and signal detection sequences are required to produce sufficient data to produce a satisfactory image.

Instead of using a T-R switch, the antenna system 13 may comprise separate transmitting and receiving coil 20 arrangements respectively connected with transmitter 17 and receiver 19.

In one embodiment of the apparatus of FIG. 1 in accordance with the present invention, the electromagnet is of the so-called four-poster bed type, i.e. the magnetic core arrangement of the electromagnet is similar in shape to a four-poster bed, as shown in FIG. 2. Thus the yoke joining the pole pieces 1 comprises horizontal spaced apart planar rectangular base and roof portions 25 and 27 joined by vertical posts 29, one at each corner, with the pole pieces 1 extending towards one another from the centre of the base and roof portions 25 and 27 respectively.

Referring to FIGS. 3, 4 and 5, the patient handling equipment of this embodiment comprises a lower horizontal rectangular planar table portion 31 mounted with its longer axis parallel to the longer horizontal axis of the magnetic core arrangement on rails or rollers 32 [(not shown)], just above the face of the lower pole piece 1, so as to be slidable in a horizontal plane in a direction 40 orthogonal to the longer axis of the core arrangement. On its upper surface adjacent a longer side the table portion 31 carries an elongated rectangular patient support member or platter 33 arranged to be slidable on the table portion 31, e.g. on rails or rollers, in the direction 45 of its longer axis, which axis is parallel to the longer axis of the table portion 31.

The patient platter 33 is thus capable of translational movement in two directions in a plane orthogonal to the direction of the magnetic field in the gap between the pole pieces 1, the two directions being respectively orthogonal and parallel to the longer axis of the platter 33, as indicated by arrows A and B in FIG. 3.

In use of the apparatus the table portion 31 is slid out from the core arrangement from the side at which the platter 33 is mounted so as to move the platter 33 in the direction of arrow A orthogonal to its longer axis to a position in which it is wholly outside the core arrangement, as shown in full lines in FIG. 3. The patient is then placed on the platter 33 and the table portion 31 slid 60 back into the core arrangement to bring the platter 33, and hence the patient's body, to a position where it extends centrally through the gap between the pole pieces, as shown in chain-dotted lines in FIG. 3. The platter 33 can then be slid along the table portion 31 in 65 the direction of arrow B, i.e. the direction of its longer axis, to bring the particular section of the patient's body it is desired to image to a position centrally between the

pole pieces 1, if necessary passing between the closer spaced pairs of the posts 29, as shown in chain-dotted lines in FIG. 4.

DMZCZ 5 The R.F. antenna system 13 is suitably carried on the patient platter 33 and where, as is normally the case, it is required to surround the patient's body, it may be of a hinged construction to allow side access to the platter 33, as illustrated in dotted lines in FIG. 5.

It will be appreciated that the form of patient handling equipment illustrated in FIGS. 3, 4 and 5 is also suitable for use with magnetic core arrangement of C-shape, as illustrated in FIG. 6.

Where the magnetic core arrangement is of so-called H-form, as illustrated in FIG. 7, i.e. the pole pieces 1 are joined by a yoke 35 of planar rectangular form with the pole pieces 1 positioned centrally on opposite limbs of the yoke 35, a patient handling equipment 37 of similar form to that illustrated in FIGS. 3 to 5 may be used. However, in this case the longer axis of the patient support platter 39 is at an acute angle to the longer axis of the core arrangement 41, as illustrated in FIG. 8, and the patient platter 39 is slidable in two orthogonal directions, indicated by arrows C and D, on a lower table 43 which is fixed with respect to the magnet core arrangement 41. The platter 39 when slid into a position adjacent the gap between the pole pieces 1 by movement in direction C orthogonal to its longer axis is then able to be slid in direction D so as to pass diagonally through the core arrangement 41 via the gap between the pole pieces 1.

In further embodiments of the invention, suitable for use with magnetic core arrangements of any of the above-described forms, the patient-handling equipment comprises a patient support member arranged for rotational motion as well as translational motion.

One such embodiment is illustrated in FIGS. 9 and 10 wherein a four-poster bed magnetic core arrangement 45 is shown by way of example. In the embodiment of FIGS. 9 and 10 the patient handling equipment comprises a horizontal planar rectangular patient support member 47 which at a central position on its underside is mounted on one end of a horizontal arm 49 for pivotal movement about a vertical axis 51. At its other end the arm 49 is, in turn, mounted for pivotal motion about a vertical axis 53 at one end of a second horizontal arm 55 whose other end is similarly pivotally connected to a flange member 57 fixed with respect to the core arrangement 45.

The support member 47 is thus capable of translational motion, with its longer axis parallel to the longer horizontal axis of the core arrangement 45, in directions orthogonal and parallel to its own longer axis, as indicated by chain-dotted lines in FIGS. 9 and 10, in exactly the same manner as the platter 33 of FIGS. 3 to 5. In addition, the support member 47 is capable of rotational movement in a horizontal plane at any position reached by the translational movement.

Such an arrangement exhibits several advantages. For example, if space permits, when the patient is removed from the core arrangement, the member 47 may be rotated through 90° to the position indicated by dotted line 59 in FIG. 9 to permit access to both sides of a patient. In addition, positioning of the patient's head-to-toe axis other than parallel to the longer axis of the core arrangement 45 is possible, and the direction of the patient's head-to-toe axis may be reversed without removing the patient from the support member 47. The latter feature may be of particular benefit if the available
